Antipsychotics, dopamine, and pain

These medications' effects on dopamine might help address chronic pain

SEBOS

Dmitry M. Arbuck, MD

Indianapolis, Indiana

Our understanding of pain mechanisms continues to evolve and, accordingly, so do our treatment strategies. The fundamental differences between acute and chronic pain were only recently recognized; this lack of recognition led to the application of acute pain treatments to chronic pain, contributing to the opioid epidemic in the United States.

With the diminishing emphasis on opioid medications, researchers are exploring other pharmacologic modalities for treating pain. Many nonopioid psychiatric medications are used off-label for the treatment of pain. Psychiatric medications play a larger role in the management of pain as pain becomes more chronic (***Table 1,***[1] ***page 26***). For simplicity, acute pain may be seen as nociception colored by emotions, and chronic pain as emotions colored by nociception. Protracted pain connects those extremes with a diminishing role of nociception and an increasing role of emotion,[1] which may increase the potential role of psychiatric medications, including antipsychotics.

In this article, I discuss the potential role of dopamine in the perception of pain, and review the potential use of first- and second-generation antipsychotics for treating various pain syndromes.

Role of dopamine in pain

There is increasing interest in exploring antipsychotics to treat chronic pain[2] because dopamine dysfunction is part

Table 1

How often psychiatric medications are used to treat various types of pain

Type of pain	Timing of pain	Algopathy (pathological pain perception)	Examples of painful conditions	Use of psychiatric medications
Acute pain (nociceptive pain)	1 to 3 months	None to mild	Bone fracture, torn muscle, migraine	Infrequent
Protracted pain (mix of nociceptive and central pain with diminishing nociception and growing central pain pathology)	3 to 6 months to years	Mild to moderate	Chronic spinal disc herniation, chronic regional pain syndrome, chronic migraine	Gradually increasing in frequency
Chronic pain (central pain mechanisms dominate)	3 to 6 months and longer	Moderate to severe	Central pain syndrome, fibromyalgia, chronic daily headaches	Common

Source: Modified from reference 1

Clinical Point

Both a lack of and excess of dopamine are associated with pain

of pathological pain perception. Excess dopamine is associated with headaches (dopamine hypersensitivity hypothesis[3,4]) and dopamine dysfunction is a part of posttraumatic stress disorder (PTSD),[5] dissociation,[6] paranoia,[7] and catastrophizing.[8] Somatic psychosis, like any psychosis, can be based on dopamine pathology. Dopaminergic neurons affect nociceptive function in the spinal dorsal horn,[9] and dopamine receptors are altered in atypical facial pain,[10] burning mouth syndrome,[11] and fibromyalgia.[12]

In normal circumstances, dopamine is fundamentally a protective neurotransmitter. In acute pain, dopamine is powerfully released, making the pain bearable. A patient may describe acute pain as seeming "like it was not happening to me" or "it was like a dream"; both are examples of dopamine-caused dissociation and a possible prediction of subsequent chronification. In chronic pain, pathological mechanisms settle in and take root; therefore, keeping protective dopamine levels high becomes a priority. This is especially common in patients who have experienced abuse or PTSD. The only natural way to keep dopamine up for prolonged periods of time is to decrease pain and stress thresholds. Both phenomena are readily observed in patients with pain. In extreme cases, self-mutilation and involvement in conflicts become pathologically gratifying.

The dopaminergic system is essential for pain control with a tissue injury.[13] It becomes pathologically stimulated and increasingly dysfunctional as algopathy (a pathological pain perception) develops. At the same time, a flood or drought of any neurotransmitter is equally bad and may produce similar clinical pictures. Both a lack of and excess of dopamine are associated with pain.[14] This is why opposite treatments may be beneficial in different patients with chronic pain. As an example, the use of stimulants[15] and bupropion[16] has been reported in the treatment of abdominal pain. And, reversely, antipsychotics, especially first-generation agents, may be associated with chronic (tardive) pain, including orofacial and genital pain.[17]

First-generation antipsychotics

First-generation antipsychotics (FGAs) have been used to treat various nonpsychiatric conditions (***Table 2, page 27***). Although they are powerful D2 receptor inhibitors, FGAs lack the intrinsic ability to counteract the unwanted adverse effects of strong inhibition. As a result, movement disorders and prolactinemia are commonly induced by FGAs. The most dangerous consequence of

Discuss this article at www.facebook.com/MDedgePsychiatry

treatment with these agents is neuroleptic malignant syndrome (NMS).

Haloperidol is prescribed widely by nonpsychiatrists, primarily to treat agitation. Intravenous haloperidol has been used for the abortive treatment of headaches.[18] Paradoxically, IV haloperidol is less likely to induce extrapyramidal symptoms (EPS) than the oral formulation because of a more pronounced anticholinergic action in IV use. Haloperidol can help relieve gastroparesis and nausea, especially in IV administration,[19] but prolonged oral administration is associated with unwanted movement problems and should be avoided.[20]

Chlorpromazine is more anticholinergic than haloperidol. It can be used in the abortive treatment of headaches (preferably via IV and IM administration), nausea, hiccups, porphyria, and serotonin syndrome, but it is very sedating and frequently produces hypotension, dangerous QT prolongation, and sensations of thought-blocking.[21]

Pimozide is reported to help with skin picking, trichotillomania, and somatic hallucinations.[22]

Droperidol, promethazine, and prochlorperazine are used off-label to treat nausea and headaches. Primary care clinicians may not be aware that these commonly used medications are antipsychotics. Similar to other FGAs, these 3 agents may produce NMS and tardive dyskinesia (TD). The same applies to the prokinetic drug metoclopramide.

Second-generation antipsychotics

Second-generation antipsychotics (SGAs) work with various serotonin receptors, offsetting and enhancing the antipsychotic function of dopamine blockade. This diminishes but does not eliminate EPS and the risk of TD. Fortunately, the risk of NMS is lower with SGAs than with FGAs. Many SGAs are FDA-approved for treating schizophrenia and other psychiatric disorders, and some have relevance for pain management (*Table 3, page 28*). Many SGAs help with depressive symptoms and are powerful mood stabilizers. As such, they may diminish central over-firing of dopaminergic and serotonergic neurons involved in the pain cascade, which in turn decreases pain transmission and perception. The downside is that in general, SGAs increase the risk of diabetes and hyperlipidemia.

Clinical Point

SGAs may diminish central over-firing of dopaminergic and serotonergic neurons involved in the pain cascade

Risperidone was the second FDA-approved SGA. Pain practitioners primarily prescribe it for treatmeant-resistant headaches, but patients with fibromyalgia and those with phantom and thalamic pain also may respond. Because risperidone's properties are similar to that of many FGAs, it may potently cause EPS, TD, and prolactinemia. Neuroleptic malignant syndrome also has been reported.[23]

Ziprasidone is frequently overlooked by clinicians who treat pain. Although ziprasidone may be sedating, it is powerful as both a preventive and abortive (in an IM formulation) agent for treatment-resistant headaches. This might be attributed to its effects on the 5HT9 receptor. It is approved for treating bipolar depression and has been prescribed to effectively treat anxiety. For patients receiving ziprasidone, QT prolongation needs to be monitored closely.[24]

Olanzapine was modeled after clozapine and is effective as a mood stabilizer and an antianxiety, antipsychotic, and sleep-promoting medication. It has a useful "mellowing" effect and helps with central pain syndrome management. Patients with fibromyalgia respond well; in some cases,

patients with phantom and thalamic pain also respond. Among SGAs prescribed to treat chronic pain, olanzapine has the most published studies. However, the downside is the risk of severe weight gain and diabetes. Usually, if a patient is already overweight, they gain less, but these patients typically are concerned about any additional weight gain.[25]

Clinical Point

By decreasing dopamine activity in the basal ganglia and limbic system, aripiprazole can improve abnormal pain perception

Aripiprazole is a partial dopamine agonist. It increases dopamine function in the prefrontal cortex, and by doing so it possibly improves cognition, mental acuity, goal-oriented activity, and attention. At the same time, it decreases dopamine activity in the basal ganglia and limbic system, improving catastrophizing, paranoia, abnormal pain perception, and multiple homeostasis functions. This combination of effects can be invaluable for some patients, but depending on individual susceptibility, aripiprazole might be too activating (causing agitation and akathisia) or too sedating.[26]

Brexpiprazole is a relative of aripiprazole, but for some patients it is better tolerated, and compliance with this medication usually is good. It partially antagonizes the D2 and 5HT1A receptors while antagonizing the 5HT2A receptors (which decreases the dopamine release in the striatum) and mimics the mechanism of action of an antidepressant. Through alpha-1-adrenergic receptor antagonism, it reduces EPS. All these effects are also part of the mechanisms of action of quetiapine, clozapine, and iloperidone, but brexpiprazole is considered to be the most alpha-1 antagonistic, which is a mechanism of action of other potential pain-controlling medications such as clonidine and tizanidine. In patients with pain who have an overactive noradrenergic system, this property may be beneficial. Its major problem stems from cytochrome P450 2D6 (CYP2D6) enzyme-dependent metabolism, which causes an approximately 5-fold increase in brexpiprazole blood level in poor CYP2D6 metabolizers. Therefore, combining brexpiprazole with CYP2D6 inhibitors such as fluoxetine, paroxetine, and duloxetine would be unwise. Aripiprazole and brexpiprazole are less associated with diabetes and sexual adverse effects than many other SGAs.[27]

Asenapine is an underutilized antipsychotic. Its mechanism of action spans multiple receptors and is less specific in individual receptor activity than other dopamine blockers. It is administered under the tongue due to poor absorption when swallowed, and its molecule has an anesthetic property that causes mouth and tongue numbness/paresthesia. This function may help patients with orofacial pain. Significant somnolence and weight gain (although less than with olanzapine) limit its use. Some patients cannot tolerate the taste.[28]

Quetiapine is prescribed rather frequently due to its significant antianxiety effect. It is also reported to be beneficial in pain control.[29] Weight gain may be severe. In doses smaller than typically administered to patients with bipolar disorder or schizophrenia, quetiapine is widely prescribed off-label for sleep. In lower doses, it acts primarily as an antihistamine (hence the sedation), but at an increased dose it activates the adrenergic system, which offsets sedation. Quetiapine antagonizes H1 histamine and 5HT2C receptors, which may explain its associated sedation and weight gain. Constipation is common. Due to its relatively low risk for EPS, quetiapine is safer to prescribe in patients with Parkinson's disease. It can cause withdrawal if abruptly discontinued, so it needs to be tapered. Quetiapine has become a commodity in the prison population because of its ability to

diminish anxiety symptoms.[30] There are also reports that quetiapine may be associated with pain induction. This is consistent with the above-mentioned phenomenon that pain is associated with both the lack and excess of dopaminergic function.[31] Pain perception is reported to be diminished in patients with schizophrenia,[32] and quetiapine may increase pain just by improving cognition.

Cariprazine is typically well tolerated because of its benign metabolic profile. It does not increase the QT interval and is not sedating. Cariprazine is a D2 and D3 partial receptor agonist. This allows the medication to inhibit overstimulated dopamine receptors (a desirable effect in pain management) and induces them when the endogenous dopamine level is low (helping with cognition, volition, and attention). Pro-cognitive effects are always beneficial for patients with pain. Cariprazine produces less EPS due to more ventral striatum vs dorsal striatum activity. Mood improvement caused by this medication is attributed to its 5HT2A, 5HT2B, and 5HT2C inverse agonism, which modulates the serotonergic system. Cariprazine will likely have a positive future in pain management because it has shown efficacy in the chronic stress model.[33]

A complex condition

No single medication or group of medications may be exclusively relied on for treating patients with chronic pain. Identifying alternatives to opioids for treating pain brings more attention to centrally-acting medications that may aid in the stabilization of the nervous system, which can decrease pathological pain perception and help patients cope with chronic painful conditions.

Clinical Point

No single medication or group of medications may be exclusively relied on for treating patients with chronic pain

Bottom Line

Antipsychotics may be a valuable asset in the treatment of chronic pain, offering a potential alternative to prescribing opioids for pain. More research is needed to identify specific ways of using dopamine blockade or dopamine enhancement to help patients with chronic pain.
